¹

The Regional Information Report Series was established in 1987 to provide an information access system for all unpublished divisional reports. These reports frequently serve diverse ad hoc informational purposes or archive basic uninterpreted data. To accommodate timely reporting of recently collected information, reports in this series undergo only limited internal review and may contain preliminary data; this information may be subsequently finalized and published in the formal literature. Consequently, these reports should not be cited without prior approval of the author or the Division of Commercial Fisheries.

AUTHORS

T.P. Zadina is a Fishery Biologist for the Alaska Department of Fish and Game, Division of Commercial Fisheries, Management and Development, Limnology Section, 2030 Sea Level Drive, Suite 205, Ketchikan, Alaska 99901-6073.

M.H. Haddix is the Regional Limnologist for the Alaska Department of Fish and Game, Division of Commercial Fisheries, Management and Development, Limnology Section, 2030 Sea Level Drive, Suite 205, Ketchikan, Alaska 99901-6073.

M.A. Cartwright is a Fishery Biologist for the Alaska Department of Fish and Game, Division of Commercial Fisheries, Management and Development, Limnology Section, 2030 Sea Level Drive, Suite 205, Ketchikan, Alaska 99901-6073.

ACKNOWLEDGMENTS

The authors wish to thank the interagency biologists on the ad-hoc committee, created from a sockeye salmon workshop held in Juneau, Alaska in 1987, for recognizing the importance of developing additional methods to assess and predict sockeye salmon production in SE Alaska. The authors also thank Ralph Spear and Jim Schromek of the U.S. Forest Service who are responsible for digitizing lake areas for the Geographical Information System using aerial and landsat photos. Thanks also to the many biologists and technicians who collected the existing data on many of the lakes discussed in this report.

ABSTRACT

Potential sockeye *Oncorhynchus nerka* salmon production for 112 anadromous lake systems in southern Southeast Alaska were calculated using an euphotic volume model developed by Koenings and Burkett (1987). Physical parameters used in this model were collected or estimated, from known values of similar lakes, for 112 lakes identified in Alaska Department of Fish and Game (ADF&G), commercial fisheries management districts 101 through 108. Compilation of all data, using this model, indicated that southern Southeast Alaska sockeye lakes have the estimated potential to produce 1.714 million adult sockeye. This production would allow 1.097 million harvestable adults with the remaining 0.617 million adults needed for escapement to maintain the maximum production. The intent of this study was to provide fisheries managers with a basic mechanism to quantify escapement and harvest goals for individual systems, subdistricts, or entire districts.

KEY WORDS: sockeye, *Oncorhynchus nerka*, Southeast Alaska, euphotic volume model, production potential model, salmon, escapement goals, harvest goals, maximum production, morphometry, euphotic zone

INTRODUCTION

Sockeye *Oncorhynchus nerka* salmon rehabilitation and enhancement programs in the state of Alaska have been ongoing since 1979. Numerous investigations have been directed toward defining relationships between limnological parameters and sockeye salmon rearing capacities (Koenings and Burkett 1987; Koenings, et al. 1989; Peltz and Koenings 1989). An euphotic volume model (Koenings and Burkett 1987) emerged from these studies as a rudimentary method to quantify the optimum sockeye salmon adult production goal; under the assumption that the limiting life history stage for sockeye is their juvenile freshwater life phase. This is the first known effort to quantify the sockeye salmon production potential of southern Southeast Alaska (Figure 1). Limitations in the physical habitat required for other life history phases were not considered in these production estimates. These data will hopefully help direct enhancement or rehabilitation programs as well as management decisions in fulfilling sockeye salmon production goals.

METHODS

Production Model

The juvenile sockeye rearing capacity estimates are based on an euphotic volume model developed by Koenings and Burkett (1987). Calculated as follows:

$$[\text{Lake Surface Area (m}^2) \cdot \text{EZD (m)}] \cdot 1,000,000^{-1} = \text{EV units}$$

The euphotic zone depth (EZD), the depth to which 1% of the subsurface light [photosynthetically available radiation (400-700 nm)] penetrates (Schindler 1971), is calculated as the y-intercept derived by regressing depth against the logarithm (ln) of the percent subsurface light. Euphotic volume (EV) is the product of the euphotic zone depth (EZD) and the lake surface area and represents the volume of water capable of photosynthesis. One euphotic volume (EV) unit is equal to one million cubic meters of water (Figure 2). This EV model is based on a set of empirical models that provide estimates of potential

juvenile and adult sockeye production. According to the model, one EV unit can sustain a maximum of 110,000 spring fry, which will produce 23,000 threshold size (2.2 g) smolt and 2,500 adult sockeye.

Analysis and Evaluation

Each lake system in this report was first identified by a group of inter-departmental biologists from the ADF&G and the National Marine Fisheries Service (NMFS) as an anadromous sockeye system. After this initial identification a complete search of data and reports for each lake was accomplished. Data were unavailable for most of the smaller sockeye salmon lakes.

Lake Area

Lake surface areas were measured using the most accurate means possible in the following order:

1. Actual lake surveys where bathymetric maps were created using depth soundings and ground measurements between prominent points. These measurements were then scaled down to drawings made from aerial photos.
2. Digitized computer analysis of aerial photos and landsat photos by the USDA - Forest Service Geographical Information System (GIS).

The lake surface areas in this report should supersede surface areas from previously reported data. Many older ADF&G, Sport Fish Division lake surveys² include lake surface areas which were merely visual estimates.

Lake Productivity

Productivity was evaluated using euphotic zone depth (EZD) which is an index of limnetic production (Koenings and Burkett 1987). Dependent on the frequency of lake limnological sampling, the most accurate means possible was used to calculate EZD. The following order represents the degree of accuracy from highest to lowest.

² Baade, R., et al., Alaska Dept. of Fish and Game, Sport Fish Division. SE Alaska Lake surveys. Unpublished.

1. Submarine photometer to measure actual incidental light levels in the water column. Usually taken throughout the year during normal limnological sampling programs. Mean of seasonal readings used for EZD.
2. Secchi disk transparency readings (SD), using a 20 cm black and white disk, usually taken during one preliminary lake survey. SD readings are converted to EZD by regression analysis for each lake type (clear or stained) (Koenings, et.al. 1987).
3. No actual lake surveys. Lake was assigned a weighted mean EZD based on known water color of the lake. The EZD assigned are weighted means based on thirty stained and five clear lakes in southern Southeast Alaska with actual data. The mean EZD is calculated as follows:

$$\overline{EZD} = \frac{\sum SA_i (EZD_i)}{\sum SA_i}$$

Where: SA_i = surface area of individual lake (i)

EZD_i = euphotic zone depth of individual lake (i)

Lakes were differentiated as stained or clear for formula. Calculated values are:

Stained = 5.0 m; Clear = 11.0 m.

Adult Production

The final intent of this paper is to estimate the potential production of adult sockeye salmon from each system for escapement and harvest. The escapement goal is the fixed number of fish required to sustain maximum adult production based on this model. The escapement goal based on the EV Model is 800 to 900 adults per EV unit (Koenings and Burkett 1987). This is a minimum required escapement. Geiger and Koenings (1991) escapement goal model calculated that Chilkat Lake, in northern Southeast Alaska, has a best escapement value based on actual spawner/ recruitment data of 1,290 adults per EV unit. For our purposes we used 900 adults per EV unit.

RESULTS

A total of 112 lakes in southern Southeast Alaska (Districts 101-108), were identified as current sockeye salmon producing systems (Table 1). Total potential adult sockeye production was estimated to be 1.714 million fish. The estimated minimum escapement goal is 617,152 to sustain maximum yields. This would allow for a potential annual harvest of approximately 1,097,161 sockeye.

Twenty lakes in District 101 have an estimated potential to produce 353,444 adults (Table 2). This would allow 226,204 adults for harvest and 127,240 for escapement. The largest potential producers in District 101 are the Bakewell Lake system (84,639 adults), McDonald Lake (83,980 adults) and Hugh Smith Lake (43,986 adults). Historically, in the late 1800's, Hugh Smith, Naha, and McDonald were the largest producers of sockeye. Hugh Smith produced more than 60,000 harvestable fish during this period; Naha averaged over 53,000 and McDonald averaged over 50,000 (Moser 1899). The Bakewell system was a non-anadromous system until 1958 when a fish pass was constructed.

Twenty-four lakes in District 102 have an estimated potential to produce 336,302 adults (Table 3). This would allow 215,233 adults for harvest and 121,069 adults for escapement. The largest potential producers in District 102 are Karta River system (95,057), Kegan Lake (66,113), Thorne River system (56,078), and Miller Lake (44,224). Historically the Karta River system was the largest producer with a harvest over 100,000 in 1906 (Moser, et al. 1907). Other historically large producers are Thorne River system, Paul Lake, Johnson Lake, and Kegan Lake all producing more than 30,000 adults in the late 1800's (Moser 1899).

Thirty-eight lakes in District 103 have an estimated potential to produce 374,289 adults (Table 4). This would allow 239,546 adults for harvest and 134,743 adults required for escapement. The largest potential producers for District 103 are Klawock Lake (123,549), Sarkar system (98,425), and Hetta Lake (70,943). District 103 has the highest production potential of all districts in this report. Historically, Hetta Lake was the largest sockeye producer in this district averaging more than 60,000 with a peak of 201,299 in the late 1800's. During this time Klawock Lake averaged 36,000, Sarkar averaged 16,000, and Klakas averaged 7,000 (Moser 1899).

Six lakes in District 104 have an estimated potential to produce 172,884 adults (Table 5). This would allow 110,645 adults for harvest and 62,239 adults for escapement. The largest producer in District 104

are the Devils Lake Head system (87,186) and Essowah Bay system (52,334). There are no historical records from this district before 1960 primarily because the area was not close to operating canneries.

Four lakes in District 105 have an estimated potential to produce 35,126 adults (Table 6). This would allow 22,481 adults for harvest with 12,645 adults needed for escapement. This is the lowest production district in southern Southeast Alaska. The largest producer in District 105 is Shipley Lake (22,877). Historically, Shipley Lake was the highest producer in the late 1800's with a peak of 6,762 adults harvested in 1892. These numbers are misleading because this system was not used for cannery operations because it was off the path of cannery steamers. These fish were primarily sold salted via a saltery located on site and sold only when the mail steamer came about (Moser 1898).

Fourteen lakes in District 106 have an estimated potential to produce 357,033 adults (Table 7). This would allow 228,502 adults for harvest and 128,531 adults required for escapement. The largest producers in District 106 are Sweetwater system (149,612), Salmon Bay Lake (47,053), and Red Bay Lake (45,174). The Sweetwater Lake system potential production is questionable because Sweetwater Lake, which is the largest lake in the system, receives salt water during high tides. The extent of this influence is unknown concerning limnetic production of this lake. Historically, Salmon Bay and Red Bay Lakes were the largest producers with annual harvests above 50,000 and 20,000 respectively in the late 1800's to early 1900's (Moser et al. 1898-1910).

Six lakes in District 107 have an estimated potential to produce 85,235 adult sockeye (Table 8). This would allow 54,550 adults for harvest and would require 30,685 adults for escapement. The largest producer in District 107 is Virginia Lake (48,819). Thoms Lake historically was the largest producer with a harvest of 17,138 in 1897 (Moser 1898).

There are no lakes in District 108. The Stikine River system (U.S. portion) in District 108 produces sockeye but cannot be evaluated with the Euphotic Volume Model.

DISCUSSION

This report presents only relative production potential estimates for each lake based on lake morphological data. Possible limitations in spawning habitat were not considered in these production estimates. A more detailed habitat analysis of the individual systems will be necessary to identify any such limitations. Harvest rates on certain southern Southeast Alaska systems have been as high as 97% (Badger-Bakewell system, 1991) of the total yearly production. These systems are unlikely to reach their production goals without changes in harvest strategies. With further data collection and analysis a more accurate estimate of production potential will result. The early historical sockeye counts by Moser et al. (1898-1910) were based on harvest numbers for individual streams, and provided total stream counts since most streams were blocked to upstream passage so all fish could be harvested. This was the period for large harvests of sockeye in southern Southeast Alaska.

Nutrient enrichment of certain lakes has also increased production dramatically. McDonald Lake has been receiving nutrient enrichment since 1982, and production has increased from an estimated average of 84,000 adults to an excess of 300,000 adults annually. The enrichment program has allowed McDonald Lake to sustain a rearing capacity which is substantially higher than prior to enrichment. Annual production from McDonald Lake, with nutrient enrichment, contributes roughly 7.5 percent of the total SSE Alaska districts 101-108 commercial harvest.

These data will hopefully help direct enhancement and/or rehabilitation programs as well as management strategies toward reaching full production potential.
