INTRODUCTION

The proposed Susitna hydroelectric project will alter the natural streamflow, thermal, and sediment regimes of the Susitna River. The river segment downstream from Devil Canyon to the Chulitna River confluence (Talkeetna) would experience notable alterations in natural occurring streamflow patterns, due to its proximity to the proposed damsites and the limited amount of influence that tributary inflows have on total discharge in this river segment. With-project mainstem discharges, as measured at the U.S. Geological Survey (USGS) Gold Creek gaging station, are expected to be lower during summer and notably higher during winter months.

Five species of Pacific salmon and 15 resident fish species utilize a variety of aquatic habitats in the Talkeetna-to-Devil Canyon reach of the Susitna River. Alteration of the natural streamflow patterns by construction and operation of the proposed Susitna hydroelectric project is expected to affect the amount and seasonal availability of the aquatic habitats presently being utilized by these species.

Knowledge of the location and amount of aquatic habitats occurring in the Talkeetna-to-Devil Canyon reach at various different mainstem discharges will facilitate forecasting the effects of reduced mid-summer streamflows on the availability of aquatic habitat to resident and anadromous fish. This report describes the surface area response of six aquatic habitat types to changes in mainstem discharge.

Aquatic habitat mapping and surface area measurements on 1 inch=1,000 feet aerial photography were used to determine the location and amount of fish habitat within the Talkeetna-to-Devil Canyon reach of the Susitna River at mainstem flows of 23,000, 16,000, 12,500, and 9,000 cubic feet per second (cfs). These discharges provide an adequate basis for estimating the magnitude of anticipated changes in the amount and availability of aquatic habitat as a result of construction and operation of the proposed project. However, this report makes no statements concerning the suitability of the habitat areas for habitation by fish, nor how the quality of these habitats may change in response to varying mainstem discharges.

METHODS

Habitat Type Designations

Riverine habitats associated with the Susitna River between Talkeetna and Devil Canyon were classified into six general categories: mainstem, side channel, side slough, upland slough, tributary mouth, and tributary. Although riverine habitat is influenced by channel geometry, these six general categories are not defined as fixed geographical locations along the river. Each habitat category has a unique set of visually recognizable attributes that respond to changes in mainstem discharge, and which are used to determine the type of aquatic habitat that occurs at a particular location. For example, an area described as a side slough habitat would be classified as side channel habitat when turbid mainstem water overtops the upstream head of the slough and inundates the former clear water area.

The six aquatic habitat categories used in this analysis are described below. These descriptions are limited to physical characteristics that can be easily recognized from the air during helicopter reconnaissance flights. A more detailed description of each aquatic habitat type has been prepared by the Alaska Department of Fish and Game (ADF&G) (1983).

Mainstem habitats are characterized by turbid, glacial water. The channel conveys more than 10 percent of the total flow at a given site.

Side channel habitats also contain turbid, glacial water. These channels convey less than 10 percent of the total flow.

Side slough habitats contain clear water. Local surface water runoff and upwelling are the primary water sources that supply clear water to the side sloughs. Side sloughs have nonvegetated upper thalwegs that are overtopped during periods of moderate to high mainstem discharge. Once overtopped, side sloughs are considered side channels.

Upland sloughs are clear water habitats that depend upon upwelling and/or local runoff as their clear water sources. Upland sloughs possess vegetated upper thalwegs that are seldom overtopped by mainstem discharge.

Tributary mouth habitats are clear water habitats that exist where tributary contributions to the mainstem are visible. These habitats are manifest as a clear water plume extending into the turbid mainstem or side channel. The size of this plume is influenced by the amount of tributary discharge and adjacent mainstem water surface elevations.

Tributary habitats are clear water reaches of tributary streams upstream of the tributary mouth habitats.

Nonwetted areas were classified as vegetated islands, exposed streambank and gravel bars, or background area. The background area consists of both wetted and nonwetted surface areas that are within the river corridor but are not relevant to the analysis. Individual surface areas were classified by using a descriptive key adapted from the ADF&G SuHydro classification index for aquatic habitat types and by incorporating staff thought process when classifying individual habitat areas during their helicopter reconnaissance flights (Figure 1).

Field Methods

Complete photographic coverage was obtained of the Talkeetna-to-Devil Canyon reach at four streamflows. Black-and-white aerial photographs were obtained at an approximate scale of 1 inch=1,000 feet with a 60 percent overlap between adjacent photos when Susitna River discharges as measured at the USGS Gold Creek gaging station (#15292000) were 23,000, 16,000, 12,500, and 9,000 cfs.

Helicopter reconnaissance flights were conducted by E. Woody Trihey and Associates over the Talkeetna-to-Devil Canyon reach at the same mainstem discharges at which the aerial photography was obtained. Three additional reconnaissance flights were conducted when mainstem discharges were 7,290, 10,600, and 20,900 cfs. During each of these reconnaissance flights, habitat types were identified using the key presented as Figure 1 and their locations were mapped on 1 inch=1,000 feet blue-line prints of the Susitna River. Dewatered gravel bars and streambank areas were

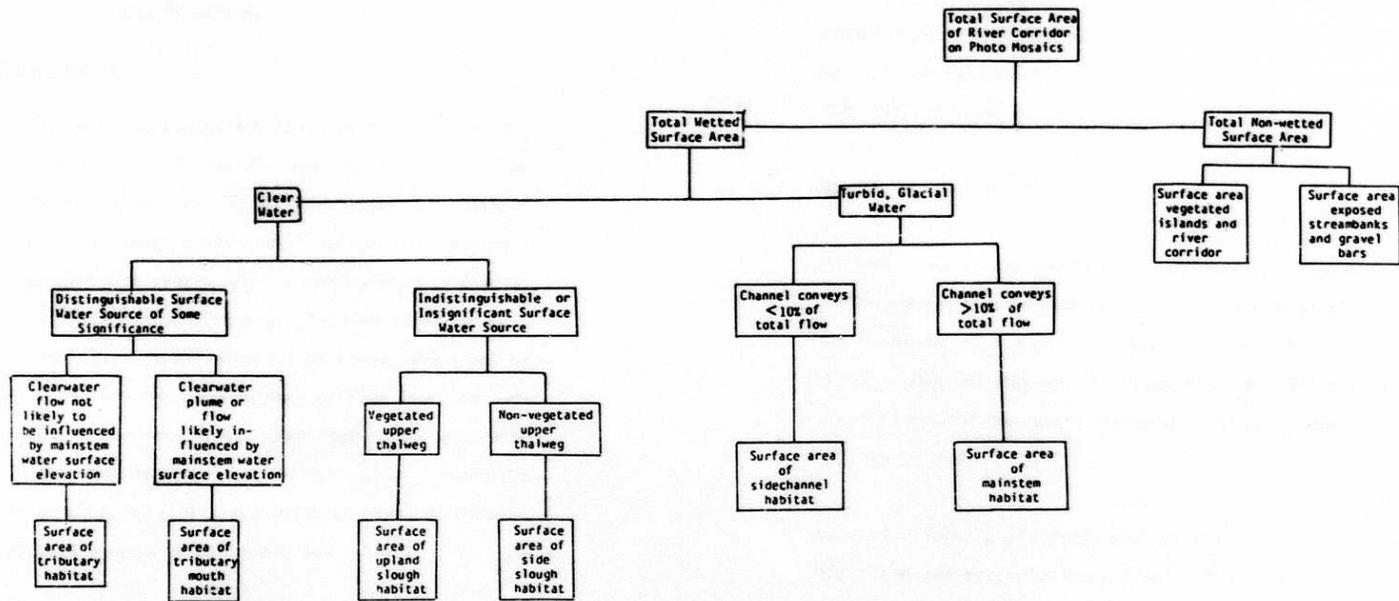

Figure 1. Key to aquatic habitat classification for the Talkeetna-to Devil Canyon reach of the Susitna River (RM 101 to 149).

sketched on the blue line prints as were boundaries of the various aquatic habitat types.

Office Procedures

Photo Plates and Enlargements

Photographic mosaics were prepared by Air Photo Tech, Inc. from the overlapping black-and-white photos to provide continuous 1 inch=1,000 feet coverage of the Talkeetna-to-Devil Canyon river segment for each of the four flows. The photo mosaics were subdivided into eighteen sections of approximately the same length, with a small amount of overlap between adjoining river sections. The same dividing lines between adjoining segments were maintained for all four flows, and a set of eighteen 4-1/2 inch by 15 inch photo plates were printed from the sectioned mosaics for each of the four flows. Each photo plate was carefully examined and areas that were too small in size on the 1 inch=1,000 feet photography to provide detailed resolution of small or complex habitats were enlarged to a scale of 1 inch=250 feet.

Habitat Type Boundaries

Aquatic habitat boundaries mapped on the blue line prints during the helicopter reconnaissance flights were transferred to individual photo plates and enlargements. Matchlines were drawn on adjoining plates to ensure that habitat areas would not be counted twice within any of the overlapping coverage near the edges of photo plates. The boundary of each enlargement area was established using identifiable features in the

photography and drawn on both the plate and the individual enlargement to ensure that areas within the enlargement could be summed and compared with the enlargement area on the plate. The external boundaries of the total area to be included in the surface area analysis (hereafter referred to as the corridor area) were defined on each plate, so that all areas within the corridor area could be totaled and compared with the total corridor area.

Digitizing

Surface area measurements were made using a Numonics Corporation Electronic Graphics Calculator and Model 2400 DigITablet. By tracing the perimeter of a given area, the area contained within the perimeter is calculated and displayed to an accuracy of 0.0001 square inches. For the 1 inch=1,000 feet scale photography, this represents an accuracy of 100 square feet.

Each individual photo plate and its accompanying enlargements were digitized and evaluated separately. The total surface area of the corridor was digitized to establish a control area. Each individual habitat area excluding those within a designated enlargement were then assigned a unique sequential number and their surface areas digitized. Replicate digitized measurements were made for each individual area to insure repeatability within 5 percent.

Following completion of these area measurements, the total surface area of enlargements appearing on the plate were digitized. Individual areas within each enlargement were then assigned a unique sequential number

following the last number assigned to an individual area on the photo plate or previous enlargement. These areas were then digitized and the individual areas totaled for comparison to the total digitized area of the enlargement.

Following completion of digitizing for a given plate, individual area measurements were summed and compared to the total area measurement for the corridor. A difference of less than 5 percent was considered acceptable. This procedure was repeated for all 18 photo plates at each of four flows. Thus, each digitized area on a photo plate or its associated enlargements had a unique identifying number associated with all four flows, and the sum total of these individual areas was within 5 percent of the total corridor area.

Data Base

Area measurements were entered into a computerized data base for storage, sorting and subsequent analysis. Each individual surface area measurement was entered as a separate record with its unique address that enabled identification by flow, photo plate (corresponding to a river mile index), and individual area number. Data were retrievable in a variety of formats: by flow, by river mile index, or by retrieving and combining specific individual areas. In this way, the influence of mainstem discharge on the surface area of specific habitat types or locations could be routinely investigated.

Correction factors were entered to standardize all measurements to a common scale of 1 inch=1,000 feet. Surface areas within all enlargement areas were divided by a factor of 16 to account for the four-fold difference in scale between 1 inch=250 feet and 1 inch=1,000 feet. Due to poor weather and associated low ceilings, the 9,000 cfs photography was flown at a scale of 1 inch=920 feet whereas the other three sets of photography were obtained at a scale of 1 inch=1,000 feet. Therefore, all surface area measurements for the 9,000 cfs photography were multiplied by a factor of 0.85 to correct for this difference in scale.

Analysis Procedures

Total surface areas were calculated for the entire control corridor between Talkeetna and Devil Canyon by aquatic habitat type for each of the four flows. Summations of surface area for the corridor and aquatic habitat types were also made by individual plate. Percentages of the total surface area represented by each habitat type was calculated for each of the four flows by river reach and individual plate.

A series of procedures were employed to evaluate the reliability of the digitizing. These procedures identified flow-dependent trends in the digitized data that would verify the accuracy and consistency of the methodology. Comparisons were made between total surface areas digitized at each of the four flows for the corridor, vegetated bar, background, and tributary areas. In addition, percentages of the total surface area represented by each aquatic habitat type were calculated as were the percentages of total surface area for exposed gravel, vegetated bars and

background area at each of the four flows. These percentages were summed and the deviation from 100 percent was determined.

The magnitude of surface area change in individual habitat types in response to changes in mainstem discharge was determined. The 23,000 cfs aerial photography was chosen as being representative of typical mid-summer discharge conditions for the Susitna River in the Talkeetna-to-Devil Canyon reach (Bredthauer and Drage, 1982), and the percent change in surface areas was calculated as measured from the mid-summer baseline of 23,000 cfs.

Finally, the Talkeetna-to-Devil Canyon reach was subdivided into four segments that reflect different geomorphological characteristics, and the surface areas of each habitat type within these segments were presented as functions of streamflow.

RESULTS

Total surface areas within the control corridor are presented in Table 1 by aquatic habitat type and sub-area for each photo mosaic. Surface area values are presented in square inches with a precision of ± 0.0001 square inches.

Surface area of side slough habitats increased with decreasing mainstem discharge. Upland slough surface area showed a declining trend with decreasing discharges.

Table 1. Surface areas (in²) within the control corridor for the Talkeetna-to-Devil Canyon reach by Flow (cfs)

HABITAT TYPE	Total Surface Area (in ²) for Streamflow Indicated			
	<u>9,000</u>	<u>12,500</u>	<u>16,000</u>	<u>23,000</u>

Total Corridor Area	455.6006*	498.9116	500.6365	476.1470

*Snow and shoreline ice complicated the digitizing of this set of photography.

Tributary mouth habitat was low at 9,000 cfs mainstem discharge, increased at flows of 12,500 and 16,000 cfs, then declined at 23,000 cfs. Surface area of vegetated bars remained relatively constant over the range of mainstem flows. Tributary habitat increased slightly with decreasing discharge.

The values presented in Table 1 were plotted to illustrate habitat types to changes in mainstem discharge as measured at the USGS Gold Creek gaging station (Figure 2). Surface areas of mainstem and side channel habitats increased with increasing mainstem discharge. Concurrently, exposed gravel bars decreased with increasing discharge.

Percentages of total surface area within the control corridor are presented in Table 2 by category for each of the four flows.

Table 3 presents the percentage change in the surface areas of each habitat type with decreasing mainstem discharge as calculated from a baseline flow of 23,000 cfs.

Figures 3-6 present the surface area response of individual habitat types to mainstem discharge in four segments of the Talkeetna-to-Devil Canyon reach. These segments are from river miles 101 to 113, 113 to 122, 122 to 138, and 138 to 149. The percentage of the total area that each habitat type represents varies for each of these river segments, but the general trends displayed by the entire study reach are also shown in these segments.

Figure 2. Surface area responses to mainstem discharge in the Talkeetna-to-Devil Canyon reach of the Susitna River (RM 101 to 149).

DISCUSSION

Air photo interpretation is highly dependent on the quality of the photography. Although clear and complete, each set of photography has particular characteristics that are a result of the time of day, date and weather conditions prevailing at the time the aerial photographic missions were flown. These characteristics can affect the extent to which certain detailed features are visible. The 9,000 cfs photography, obtained on October 10, 1983, was taken after ice had begun to form on the river and after snow had covered the ground. In some cases, this made the determination of the water's edge more difficult. In other cases, particularly for upland sloughs, the contrast of open water with the snow combined with the lack of foliage on the deciduous vegetation better defined the perimeter of the slough.

The 23,000 cfs photography, obtained on June 1, 1982, was taken with the sun at a high angle resulting in few shadows. In addition, the deciduous vegetation had not fully leafed-out, enabling better definition of water's edge and slough boundaries.

The 12,500 and 16,000 cfs photography, obtained on September 11, 1983 and September 6, 1983, respectively, were taken with the sun at a lower angle, resulting in more shadows. These shadows, in combination with fully-leafed out vegetation, made some surface area delineations difficult.

The procedures employed to evaluate the accuracy and reliability of the digitizing corroborated our techniques. Total surface areas of the control corridors were compared at four discharges and were found to deviate from 1.1 to 5.3 percent from the arithmetic mean for the Talkeetna-to-Devil Canyon reach. This indicates that a high level of precision was maintained during the digitizing and good replicability exists between the four sets of aerial photography. Total surface areas for vegetated bars and background areas were compared between the four flows and were found to remain relatively constant. This would be expected due to the limited influence of the active channels on these areas.

Habitat categories used in this study represent a set of visually recognizable, streamflow dependent physical characteristics occurring in a particular area at a given time. These categories are not fixed geographical locations. Good examples of the flow-dependent nature of habitat categories are side sloughs and side channels. Side sloughs, by definition, are clear-water habitats with upwelling and surface water runoff being the major source of water. An exposed alluvial berm often separates the head of the slough from the active channel. When mainstem discharge increases and the berm is overtopped, turbid mainstem water flows into the channel and inundates the former clear water habitat. The channel now fits the description of a side channel habitat.

As mainstem discharge decreases, areas classified as side channels may become cutoff from mainstem flow and become clear water habitats. These areas are then classified as side sloughs. This classification makes no statement concerning habitat quality. Insufficient time and resources

were available to field verify the presence or absence of upwelling in these areas. Field verification is necessary to determine quality and suitability of these areas for fish habitat.

With decreasing mainstem discharge, the backwater effects at the downstream end of the sloughs were reduced. Thus the total surface area of the slough was increased as the sloughs flowed farther out to meet with mainstem or side channel water.

The primary effects of a reduction in mainstem discharge are associated with the reduction of mainstem and side channel habitat surface area and an increase in the amount of side slough and exposed gravel bar surface area. The changes in side channel and side slough surface areas reflect both the dewatering of areas as the flow is decreased and the change in classification.

Surface areas of tributary streams were summed and found to increase slightly at a mainstem discharge of 9,000 cfs. As widths of the mainstem channels decrease with decreasing discharge, tributaries must flow a somewhat greater distance and, therefore, tributary surface area increased at low mainstem discharge. Tributary mouth habitat is dependent on tributary flow as well as mainstem discharge and channel geometry. The reduction of tributary mouth habitat at 9,000 cfs may reflect a greater influence from low tributary flows that occurred in October rather than the influence of mainstem channel geometry.
